INTRODUCTION
Diarrhoeal disease is an important public health problem among under-five children in developing countries. Global estimates of the mortality due to diarrhoea have shown a steady decline since 1980s. However, diarrhoeal diseases still continue to be an important cause of morbidity and mortality worldwide in spite of all advances in health technology, improved management, and increased use of oral rehydration therapy in the past decades. Morbidity due to diarrhoea has not shown a parallel decline in comparison to mortality trends, and global estimates remain between two and three episodes of diarrhoea per under five year child per year. ¹ Millenium Development Goal - 4 aims to reduce childhood mortality by 2/3 by the year 2015 and previous studies, however, show minimal progress in this regard. So efforts must be made to review existing strategies and formulate newer ones.²

There are multiple reasons for poor declining trend of diarrhoeal diseases especially in developing countries with the environmental sanitation issues contributing a major part of it. A recent review highlighted the fact that there is a need for prioritisation of certain interventional strategies with respect to environmental sanitation in India.³ This is in view of changing pattern of exposure to risk factors at various levels for water borne diseases including urbanisation and industrialisation. Because of the above findings, it is important to analyse the diarrhoeal disease morbidity pattern and factors associated with it, preventive and control strategies with recent developments, so that appropriate control measures can be adopted at various levels in the community.

ABSTRACT
Recent data showed that there is no much reduction in diarrhoea related morbidity in developing countries. This is important in view of the Millennium Developmental Goal (MDG) to be achieved by 2015. This study reviewed and analyzed after gathering the recent literature information from Pubmed, internet and other sources. The authors discussed public health issues related to diarrhoeal diseases that include problem burden, determinants, intervention strategies, management, prevention and recent developments for control of diarrhoea among under-five children in developing countries. The study emphasizes the need for strengthening of comprehensive diarrhoeal disease prevention strategy at primary level including improvement of water quality, hygiene and sanitation, along with provision of oral rehydration solution and zinc supplements, and research in the field of vaccine and cost effective interventions.

KEY WORDS
Diarrhoea, Developing countries, Situational analysis
METHODS

Recent data was collected from Google search engine, Pubmed and others. Key words used were diarrhoeal diseases, developing countries, problem burden, risk factors, aetiology, interventional strategies, and vaccines. Data pertaining to developing countries after the year 2000 was collected, summarised and analysed for discrepancies. Information was described in terms of problem burden, determinants, intervention strategies, management, prevention and recent developments for control of diarrhoea among under-five children.

Problem Burden and determinants

Diarrhoeal disease was the second leading cause of death among under-five children in low-income countries in 2004 after pneumonia and it kills 1.5 million children every year. In developing countries, children under three years old experience on average three episodes of diarrhoea every year. A review of the incidence and prevalence of acute gastrointestinal illness from 33 studies in developed countries reported it to be ranging from 0.1 to 3.5 episodes per person-year. In India, the proportionate mortality due to diarrhoea was 9.1% and the estimated projection of Years of Life Lost (YLL) will increase from 1,68,896 in 2006 to 1,95,046 in 2016 among 0 to 6 years age group.

The Egypt and Ethiopia studies showed that 33.6%, 24.5% and 14% of the acute diarrhoeal diseases had persistent diarrhoea. The risk factor analysis were varied in different studies. A hospital based data from Bangladesh reported that more diarrheal patients admitted were above five years of age (64%) than those below five years of age (36%). About 60% of the patients above five years of age had severe dehydration compared with only 9% of patients under five years of age.

Egypt study reported that in order of contribution to risk prediction, household meat consumption, mother’s age at the time of birth of the child, child’s age, and father’s illiteracy were significant factors, while Ethiopia study found that well source of water and acute respiratory infections (ARI) in the previous two weeks were found to be significantly associated with occurrence of diarrhoeal disease in the logistic regression analysis. Another study found that use of cover material during drinking water transportation, faeces seen around the pit-hole and bottle feeding were the only significant variables on multivariate analysis. In contrast to this another study in Ethiopia found that young age, male gender, living in a house with fewer number of rooms, and obtaining water from storage containers by dipping showed statistically significant association with diarrheal morbidity while type of water source, amount of water consumed, and latrine availability were not found to be significant risk factors. Iraq study showed that 6.9% of under-five children also had acute respiratory infection (ARI) in the last two weeks and diarrhoea was associated with age of child, area of residence, maternal education, source of water, toilet facility, disposal of children’ stool and disposal of dirty water. Indian studies found that household member with cholera during the period of surveillance, young age, lower educational level and non-potable water at storage points was associated with water borne diseases.

At the same time it is important to look for the quality of water distribution system from the source. As found out in Borakpur, India, bacteriological pollution of drinking water supplies due to the infiltration of contaminated water through cross connection, leakage points, and back siphoning caused diarrheal illness. The significant water risk factors as identified were the mode of water transportation, and the poor handling of water at the household level, including lack of or inappropriate water treatment methods. These, combined with the low education level further pre dispose the under five children to diarrhoea. Also, washing and purifying fruit and vegetables; presence of wastewater in the street; refuse storage, collection and disposal; domestic water reservoir conditions; faeces disposal from swaddles; presence of vectors in the house and flooding in the lot were found to be associated with diarrhoea. Amongst households storing municipal water proven to be safe at source, adhering to the best storage practices did not translate into lower incidence rates as compared to those with relatively unsafe practices. The explanation lay in factors which were external to the home and beyond the control of the affected household. Thus, household level behavioural factors such as storage practises should not be analysed in isolation as determinants of diarrhoeal illness particularly...
when pitted against stronger neighbourhood and external determinants.\textsuperscript{22}

Aetiology

A study in Bangladesh found that the most prevalent pathogen isolated was Vibrio cholerae O1 (23%) followed by ETEC (11%). About 8% of cholera infection was seen in infants with the youngest children being one month of age while in the case of ETEC the rate was 11%. Of the isolated ETEC strains, the enterotoxin type were almost equally distributed; ST accounted for 31% of strains; LT/ST for 38% and LT for 31%.\textsuperscript{18} During the dry season, acute watery diarrhoea is the most common type of diarrhoea in children under five years in a study in Tanzania and overall, bacteria and viruses contributed equally accounting for 33.2% and 32.2% of all the cases, respectively.\textsuperscript{23} Of the estimated 165 million cases of Shigella diarrhoea that occur annually, 99% occur in developing countries out of which 69% of episodes occur in children under five years of age. Moreover, of the ca.1.1 million deaths attributed to Shigella infections in developing countries, 60% of deaths occur in the under-five age group.\textsuperscript{24}

A recent study from China showed that 46.48% of diarrhoea among young children are due to viral aetiology with rotavirus infections were the most common, followed by adenovirus infections, norovirus infections and astrovirus infections. Children younger than one year old were the most susceptible population to viral infections (87.9%).\textsuperscript{25} Uganda and Turkey studies showed that prevalence of rotavirus infection was 45.4% and 44.4%.\textsuperscript{26, 27}

Another hospital based study from India found that about 3.6% of the cases were positive for E. histolytica. No seasonality was observed although in the neighboring tropical country Bangladesh, a typical seasonality of E. histolytica infection was noticed.\textsuperscript{28} A Nigerian study showed that out of 300 under-five children with diarrhea, 70 (23.3%) had parasites. There were 18 (6%) helminthes and 52 (17.3%) protozoa. Malnutrition and low socio-economic status are risk factors.\textsuperscript{29} A recent study in South Asia, South East Asia and Far East found that prevalence of G. lamblia varied markedly between studies illustrating higher levels in the urban than in the rural areas, more among poor communities, slightly higher in males than in females with age range of 2-5-year-old children, and among university students, old-aged people, HIV-positive patients, and gastric carcinoma patients.\textsuperscript{30} Prevalence rates of Giardia infection in patients with diarrhoea range from 0.4% to 70%, and asymptomatic cyst passage has been found to be as high as 50% in rural southern India.\textsuperscript{31}

Intervention strategies

A systematic review showed that based on current evidence, washing hands with soap can reduce the risk of diarrhoeal diseases by 42-47%\textsuperscript{32, 33}. Compared with children living in households where persons prepared food without washing their hands, children living in households where the food preparer washed at least one hand with water only (odds ratio =0.78), washed both hands with water only (OR=0.67), or washed at least one hand with soap (OR=0.30) had less diarrhoea. In households where residents washed at least one hand with soap after defecation, children had less diarrhoea (OR=0.45). There was no significant association between hands washing with or without soap before feeding a child, before eating, or after cleaning a child’s anus who defecated and subsequent child diarrhoea and hand washing with water alone can significantly reduce childhood diarrhoea.\textsuperscript{34} Having water available at the place to wash hands after toileting (odds ratio = 2.2) and having soap available at the place to wash hands after toileting (odds ratio = 2.1) were associated with washing both hands with soap after fecal contact.\textsuperscript{35} These observations suggest that hand washing before preparing food is a particularly important opportunity to prevent childhood diarrhoea. With an intense community-based intervention and supplies provided free of cost, each of the home-based interventions significantly reduced diarrhoea. There was no benefit by combining hand washing promotion with water treatment.\textsuperscript{36}

Access to improved sanitation was associated with lower mortality (OR = 0.77), a lower risk of child diarrhoea (OR = 0.87) and a lower risk of mild or severe stunting (OR = 0.73). Access to improved water was associated with a lower risk of diarrhoea (OR = 0.91) and a lower risk of mild or severe stunting (OR = 0.92), but did not show any association with non-infant child mortality (OR = 0.97).\textsuperscript{37} The long-term impact of the floods was not clearly marked in the overall prevalence of diarrhoea with the exposed group having prevalence of 55.1% as against 56.2% in the unexposed group of children under five.\textsuperscript{38} diarrhoea is positively correlated with earth eating ($r = 0.306$), presence of human faeces in the yard ($r = 0.587$), presence of animal faeces in the yard ($r = 0.225$) and the index child not wearing loincloth ($r = 0.471$).\textsuperscript{39}

The effect of increasing maternal education appears to be more protective for children in wealthy families than for children in poor families. Conversely, improvements in economic status reduce health risks more for children whose mothers are better educated. Father’s education is protective and operates independently of economic status. Our findings imply that poverty alleviation efforts occurring in concert with programs to educate women and girls will be more effective for improving children’s health than either approach alone.\textsuperscript{40}

Newly available data set District Level Household Survey 3 to quantify the impact of access to improved sanitation on diarrheal morbidity for children less than 5 years of age in India found that access to improved sanitation reduces the risk of contracting diarrhoea by 2.2 percentage points. There is considerable heterogeneity in the impacts of improved sanitation and the magnitude of the treatment effect differs largely by hygiene behaviour.\textsuperscript{41}
In case of persistent diarrhoea, micronutrient supplementation, algorithm based diet regimens, and good supportive care are sufficient in most children with above six months of age. More data are needed to optimize the management of diarrhoea and highlight the research priorities at a global level; such priorities include improved recommendations on oral rehydration solution composition, and the re-evaluation of therapeutic options in the light of new trials. Therapeutic strategies need to be assessed in different settings, and pharmaco-economic analyses based on country-specific data are needed.

CONSEQUENCES

Diarrhoea is a contributing factor of anaemia and malnutrition among young children. Diarrhoea may contribute substantially the burden of Acute Lower Respiratory tract Infection in malnourished populations. The absence of peripheral pulses even after full rehydration, severe malnutrition, hypoxaemia, lobar pneumonia and hypernatraemia are independent predictors of death among the under-five children with diarrhoea admitted to critical care ward of a resource-limited setting in Bangladesh. Pneumonia was the most common immediate cause of death followed by acute diarrhoea and malaria each contributing for 23% of deaths.

Recent developments

The vaccine for rota virus has been launched in 62 countries and has been included the national immunization schedule in 11 countries. The Strategic Advisory Group of Experts (SAGE) recommends the inclusion of rotavirus vaccination of infants into all national immunization programs. The vaccine should be administered promptly after reconstitution as a 1ml oral dose. The vaccine should be given in two doses. The first dose should be administered at the age of 6 weeks and no later than at the age of 12 weeks. The interval between the 2 doses should be at least four weeks. All the studies concluded that rotavirus immunization is cost effective but may not be affordable for the developing world at present. Developing countries will definitely rely on financial support from international organizations to introduce rotavirus vaccination.

Constant antibiotic surveillance is warranted as bacteria were highly resistant to various antimicrobial agents including co-trimoxazole and erythromycin which are currently recommended for empiric treatment of diarrhoea. New methods for prevention, management, and treatment of diarrhoea-including an improved oral rehydration formulation, zinc supplementation, and rotavirus vaccines-make now the time to revitalise efforts to reduce diarrhoea mortality worldwide. The addition of zinc and prebiotics to ORS limits diarrhoea duration in children. The incidence of diarrhoea showed a 13% reduction with preventive zinc supplementation. Preventive vitamin A supplementation reduces all-cause and diarrhoea specific mortality in children 6-59 months of age in community settings in developing countries.

The oral killed WC/rBS cholera vaccine (DukoralTM) was found to prevent 23% of all diarrhoea episodes and 52% of episodes due to ETEC in Finnish tourists visiting Morocco. This protection was reported, however, not to last more than a few months. The protective efficacy of the rCTB-CF ETEC vaccine was assessed in two larger placebo-controlled Phase III trials in American travellers going to Mexico and Guatemala. The only paediatric study to assess efficacy of the rCTB-CF ETEC vaccine was undertaken in rural Egypt with 350 children of 6-18 months old. Several other approaches are being pursued to develop specific ETEC vaccines using a new delivery technology, the transcutaneous immunization patch. The introduction of TF vaccines in routine vaccination programs in Asia would be highly beneficial in view of the burden of disease and cost of illness to governments and individuals. However, most developing countries are uncertain of their true TF disease burden, due to lack of rapid diagnostic tools, infrequency of laboratory testing and poor reporting system. So far, only two countries, China and Vietnam, have incorporated typhoid vaccination into their routine immunization programs, and only in a limited fashion. Two new vaccines are currently licensed and widely used worldwide, a subunit (Vi PS) vaccine administered by the intramuscular route and a live attenuated S. typhi strain (Ty21a) for oral immunization.

As the majority of childhood diarrhoeas are caused by V. cholerae, Shigellae dysenteriae type 1, rotavirus and enterotoxigenic Escherichia coli (E. coli) which have a high morbidity and mortality, vaccines against these organisms are essential for the control of epidemics. A strong political will with appropriate budgetary allocation is essential for the control of childhood diarrhoeal diseases in India, a formidable task in a country with a population of over one billion.

CONCLUSION

With high morbidity and mortality prevailing among children in developing countries due to diarrheal diseases, achieving Millennium Development Goal 4 (MDG 4), which aims to reduce the global under-five mortality rate by two thirds between 1990 and 2015, will require additional efforts. The governments should focus on comprehensive diarrhoeal disease control strategy, including improvement of water quality, hygiene, and sanitation; provision of oral rehydration solution and zinc supplements; overall improved case management and research in the field of cost effective interventions. Existing public health programs should develop effective approaches to promote hand washing that cost less and can be used to reach millions of at risk households. A strong political will with appropriate budgetary allocation along with monitoring and follow up evaluation are essential for the control of childhood diarrhoeal diseases in developing countries.
